Uncertainty Quantification in Probabilistic Air Quality Sensor Fusion

Gabriel Oduori

December 27, 2025

Abstract

Uncertainty quantification (UQ) is critical for trustworthy air quality predictions from multi-source sensor fusion. This chapter develops and compares two probabilistic approaches: (1) Sparse Variational Gaussian Process (SVGP) fusion (FusionGP), and (2) Hybrid Generalized Additive Model with State Space Model (GAM-SSM-LUR). We decompose total uncertainty into epistemic (model) and aleatoric (measurement noise) components, enabling principled calibration assessment. Rigorous evaluation on Los Angeles Basin data shows both models achieve well-calibrated predictions (PICP $> 94\%$), with FusionGP excelling in spatial extrapolation (CRPS $= 4.1$) and GAM-SSM offering superior interpretability and computational efficiency. We demonstrate automated out-of-distribution detection and quantify uncertainty during model transfer across geographic domains. Open-source implementations are provided for reproducibility.

1 Introduction

1.1 Motivation: Uncertainty in Air Quality Monitoring

Air quality predictions without uncertainty estimates are insufficient for public health decision-making (**?**). An estimated $PM_{2.5}$ concentration of 35 μg/m^3 with uncertainty ± 2 μg/m^3 indicates reliable "Moderate" air quality, while the same estimate with ± 20 μg/m^3 uncertainty spans from "Good" to "Unhealthy," rendering it unsuitable for health advisories.

Key challenges:

- Multi-source heterogeneity: EPA regulatory monitors (high accuracy, sparse), low-cost citizen science sensors (high density, variable calibration), satellite retrievals (global coverage, indirect measurement)
- Spatial-temporal variability in uncertainty
- Model selection without rigorous UQ comparison

1.2 Multi-Source Sensor Fusion Challenge

We address the fusion of three air quality data sources:

Research question: How do we optimally combine these sources while properly quantifying uncertainty?

Table 1: Air quality sensor characteristics

Source	**Accuracy**	**Density**	**Uncertainty (σ)**
EPA monitors	High (FEM/FRM)	Sparse (10–50 km)	5–10%
Low-cost sensors	Variable	Dense (100–500 m)	15–30%
Satellite (AOD)	Medium	Global (1–10 km)	20–50%

1.3 Chapter Scope and Contributions

This chapter makes the following contributions:

1. **Two complementary UQ frameworks**:
   - FusionGP: GP-based probabilistic fusion with epistemic/aleatoric decomposition
   - GAM-SSM-LUR: Interpretable hybrid model with component-wise uncertainty
2. **Rigorous comparative evaluation**: Head-to-head calibration comparison on identical datasets using PICP, ECE, CRPS, and sharpness metrics
3. **Out-of-distribution detection**: Automated spatial domain identification and uncertainty adjustment for extrapolation
4. **Transfer learning UQ**: Uncertainty decomposition during geographic domain transfer
5. **Open-source implementation**: Reproducible code for uncertainty decomposition, calibration evaluation, and OOD detection

Chapter organization: Sections 2–4 establish UQ foundations and calibration metrics. Sections 5–6 detail the two model implementations. Section 7 presents comparative evaluation. Section 8 addresses transfer learning UQ. Sections 9–11 provide applications, limitations, and conclusions.

2 Uncertainty Quantification Fundamentals

2.1 Types of Uncertainty

Following **?**, we distinguish:

Definition 1 (Epistemic Uncertainty)**.** *Uncertainty due to lack of knowledge about the system, reducible with more data or better models. Also called* model uncertainty *or* systematic uncertainty*.*

Definition 2 (Aleatoric Uncertainty)**.** *Inherent randomness in the system that cannot be reduced, even with perfect knowledge. Also called* statistical uncertainty *or* irreducible uncertainty*.*

In air quality sensor fusion:

- **Epistemic ($\sigma^2_{\textbf{epistemic}}$)**: Uncertainty about the true $PM_{2.5}$ field due to sparse observations, model misspecification, or unknown hyperparameters
- **Aleatoric ($\sigma^2_{\textbf{aleatoric}}$)**: Sensor measurement noise, atmospheric turbulence, sub-grid variability

Total uncertainty decomposes as:

$$\sigma^2_{\text{total}} = \sigma^2_{\text{epistemic}} + \sigma^2_{\text{aleatoric}} \tag{1}$$

This decomposition guides data collection: epistemic uncertainty indicates where more observations are needed, while aleatoric uncertainty represents fundamental limits.

2.2 Bayesian Framework for Multi-Source Fusion

Bayesian inference provides a principled framework for combining prior knowledge with sensor measurements (**?**). Given state $\mathbf{x}$ and measurement $\mathbf{z}$:

$$p(\mathbf{x}|\mathbf{z}) = \frac{p(\mathbf{z}|\mathbf{x})p(\mathbf{x})}{p(\mathbf{z})} \propto p(\mathbf{z}|\mathbf{x})p(\mathbf{x}) \tag{2}$$

where:

- $p(\mathbf{x})$: Prior belief (e.g., spatial smoothness)
- $p(\mathbf{z}|\mathbf{x})$: Likelihood (sensor model)
- $p(\mathbf{x}|\mathbf{z})$: Posterior belief (updated estimate)

For multiple conditionally independent sensors $\mathbf{z}_1, \ldots, \mathbf{z}_n$:

$$p(\mathbf{x}|\mathbf{z}_1, \ldots, \mathbf{z}_n) \propto p(\mathbf{x}) \prod_{i=1}^{n} p(\mathbf{z}_i|\mathbf{x}) \tag{3}$$

The product of likelihoods naturally weights sensors by precision: high-accuracy sensors (narrow likelihoods) dominate over uncertain ones (broad likelihoods).

2.3 Uncertainty Representation

We represent posterior distributions parametrically:

Gaussian representation:

$$p(\mathbf{x}|\mathbf{z}) = \mathcal{N}(\mathbf{x}|\boldsymbol{\mu}, \boldsymbol{\Sigma}) \tag{4}$$

where $\boldsymbol{\mu}$ is the posterior mean (point estimate) and $\boldsymbol{\Sigma}$ is the posterior covariance (uncertainty).

Predictive distribution at new location $\mathbf{x}_*$:

$$p(y_*|\mathbf{x}_*, \mathcal{D}) = \mathcal{N}(y_*|\mu(\mathbf{x}_*), \sigma^2(\mathbf{x}_*)) \tag{5}$$

The predictive variance $\sigma^2(\mathbf{x}_*)$ quantifies total uncertainty, which we decompose into epistemic and aleatoric components (Sections 5–6).

3 Calibration Metrics

Calibration metrics assess whether uncertainty estimates are reliable (**?**). Well-calibrated models produce 95% prediction intervals that contain the true value 95% of the time.

3.1 Prediction Interval Coverage Probability (PICP)

Definition 3 (PICP)**.** *The fraction of observations falling within predicted confidence intervals:*

$$PICP(\alpha) = \frac{1}{N}\sum_{i=1}^{N} \mathbb{1}\left[y_i \in [\mu_i - z_{\alpha/2}\sigma_i, \mu_i + z_{\alpha/2}\sigma_i]\right] \tag{6}$$

where $z_{\alpha/2}$ is the standard normal quantile for confidence level α.

Ideal calibration: $\text{PICP}(\alpha) \approx \alpha$ (e.g., $\text{PICP}(0.95) \approx 0.95$).

3.2 Expected Calibration Error (ECE)

ECE measures average deviation from perfect calibration across multiple confidence levels:

$$\text{ECE} = \frac{1}{K}\sum_{k=1}^{K} |\text{PICP}(\alpha_k) - \alpha_k| \tag{7}$$

where $\alpha_1, \ldots, \alpha_K$ are typically $\{0.1, 0.2, \ldots, 0.9\}$. Lower ECE indicates better calibration.

3.3 Continuous Ranked Probability Score (CRPS)

CRPS is a proper scoring rule that jointly evaluates accuracy and uncertainty (**?**):

For Gaussian predictions $\mathcal{N}(\mu, \sigma^2)$ and true value y:

$$\text{CRPS}(y, \mu, \sigma) = \sigma\left[\frac{z}{\sqrt{\pi}} + z(2\Phi(z) - 1) - \frac{1}{\sqrt{\pi}}\right] \tag{8}$$

where $z = (y - \mu)/\sigma$ and Φ is the standard normal CDF. Lower CRPS indicates better probabilistic predictions.

3.4 Sharpness

Sharpness measures prediction confidence via average interval width:

$$\text{Sharpness}(\alpha) = \frac{1}{N}\sum_{i=1}^{N} 2z_{\alpha/2}\sigma_i \tag{9}$$

Lower sharpness is better (more confident), but only when maintaining good calibration. Optimizing sharpness alone leads to overconfidence.

4 Air Quality Sensor Models

4.1 EPA Regulatory Monitors

Characteristics: Federal Equivalent/Reference Methods (FEM/FRM), quarterly calibration, high maintenance.

Likelihood model:

$$p(z_{\text{EPA}}|x) = \mathcal{N}(z_{\text{EPA}}|x, \sigma^2_{\text{EPA}}) \tag{10}$$

where $\sigma_{\text{EPA}} \approx 0.05 - 0.1 \times x$ (5–10% relative uncertainty).

Spatial representativeness: $\sigma_{\text{spatial}} = 2 - 10$ km (varies by urban/rural context).

4.2 Low-Cost Citizen Science Sensors

Characteristics: Optical particle counters (e.g., PurpleAir), susceptible to humidity, calibration drift.

Corrected measurement:

$$z_{\text{corrected}} = \frac{z_{\text{raw}}}{1 + \kappa \cdot \text{RH}^2} \tag{11}$$

where $\kappa \approx 0.24$ and RH is relative humidity (0–1).

Likelihood model with calibration:

$$p(z_{\text{LC}}|x) = \mathcal{N}(z_{\text{LC}}|ax + b, \sigma_{\text{LC}}^2) \tag{12}$$

where a, b are learned calibration parameters and $\sigma_{\text{LC}} \approx 0.15 - 0.30 \times x$ (15–30%).

Quality weighting: Penalize high humidity (RH > 0.8), old data (> 24 hours), uncalibrated sensors.

4.3 Satellite Aerosol Optical Depth (AOD)

Characteristics: Column-integrated aerosol (MODIS, Sentinel-5P), requires conversion to surface $\text{PM}_{2.5}$.

AOD-to-$\text{PM}_{2.5}$ conversion:

$$\text{PM}_{2.5} = \eta \cdot \tau \cdot \frac{\text{BLH}}{\text{BLH}_{\text{ref}}} \tag{13}$$

where τ is AOD, η is a regional scaling factor (20–120 $\mu\text{g/m}^3$ per AOD unit), and BLH is boundary layer height.

Likelihood model:

$$p(\tau_{\text{sat}}|\text{PM}_{2.5}) = \mathcal{N}\left(\tau_{\text{sat}} \middle| \frac{\text{PM}_{2.5} \cdot \text{BLH}_{\text{ref}}}{\eta \cdot \text{BLH}}, \sigma_\tau^2 + \sigma_\eta^2\right) \tag{14}$$

Quality flags: Reject cloud-contaminated pixels (cloud fraction > 0.2), low AOD (< 0.1), high solar zenith angle ($> 70°$).

5 FusionGP: Sparse Variational Gaussian Process Fusion

5.1 Sparse Variational GP Architecture

Gaussian Process prior:

$$f(\mathbf{x}) \sim \mathcal{GP}(m(\mathbf{x}), k(\mathbf{x}, \mathbf{x}')) \tag{15}$$

Kernel function (separable spatial-temporal):

$$k(\mathbf{x}, \mathbf{x}') = k_{\text{spatial}}(s, s') \times k_{\text{temporal}}(t, t') \tag{16}$$

where both use Matérn-3/2:

$$k_{\text{Matérn}}(r) = \sigma^2 \left(1 + \frac{\sqrt{3}r}{\ell}\right) \exp\left(-\frac{\sqrt{3}r}{\ell}\right) \tag{17}$$

with ℓ as lengthscale and $r = |\mathbf{x} - \mathbf{x}'|$.

Multi-source likelihood:

$$p(\mathbf{y}|f) = \prod_{i=1}^{n} p(y_i|f(\mathbf{x}_i), s_i) \tag{18}$$

where $s_i \in \{\text{EPA}, \text{LC}, \text{SAT}\}$ determines noise variance $\sigma^2_{s_i}$.

Sparse approximation with M inducing points :

$$q(f) = \int p(f|\mathbf{u})q(\mathbf{u})d\mathbf{u} \tag{19}$$

where $\mathbf{u} = f()$ and $q(\mathbf{u}) = \mathcal{N}(\mathbf{m}, \mathbf{S})$ is variational.

Computational complexity: $O(NM^2)$ instead of $O(N^3)$ for exact GP, enabling fusion of $N > 10^5$ observations with $M = 500$ inducing points.

5.2 Uncertainty Decomposition in SVGP

Predictive distribution at test point $\mathbf{x}_*$:

$$p(f_*|\mathbf{x}_*, \mathcal{D}) = \mathcal{N}(f_*|\mu_*, \sigma^2_{\text{epistemic}}) \tag{20}$$

Epistemic uncertainty (GP posterior variance):

$$\sigma^2_{\text{epistemic}}(\mathbf{x}_*) = k(\mathbf{x}_*, \mathbf{x}_*) - \mathbf{k}_*^T \mathbf{K}_{uu}^{-1} \mathbf{k}_* \tag{21}$$

where $\mathbf{k}_* = k(\mathbf{x}_*,)$ and $\mathbf{K}_{uu} = k(,)$.

Aleatoric uncertainty (observation noise):

$$\sigma^2_{\text{aleatoric}} = \sigma^2_{\text{noise}}(s) \tag{22}$$

where s is the source type (EPA/LC/SAT).

Total predictive variance:

$$\sigma^2_{\text{total}}(\mathbf{x}_*) = \sigma^2_{\text{epistemic}}(\mathbf{x}_*) + \sigma^2_{\text{aleatoric}} \tag{23}$$

Implementation:

```
from src.uncertainty import UncertaintyDecomposer

decomposer = UncertaintyDecomposer(model_type='svgp')
components = decomposer.decompose_svgp(fusionGP_model, X_test)

# Extract components
sigma_epistemic = components.epistemic
sigma_aleatoric = components.aleatoric
epistemic_fraction = components.epistemic_fraction

print(f"Mean epistemic fraction: {epistemic_fraction.mean():.1%}")
```

Listing 1: Uncertainty decomposition with FusionGP

Key findings (Figure **??**):

- **Within 1 km of EPA monitors:** Aleatoric dominates (65%), epistemic 35%
- **1–5 km:** Balanced (50%/50%)
- **Beyond 5 km:** Epistemic dominates (70%), indicating need for more observations

Figure 5.1: FusionGP Uncertainty Decomposition

(a) Epistemic uncertainty map
(b) Aleatoric uncertainty map
(c) Epistemic fraction by distance from sensors

Figure 1: Spatial decomposition of uncertainty for FusionGP on LA Basin. Epistemic uncertainty (model uncertainty) increases with distance from observations, while aleatoric uncertainty (measurement noise) remains relatively constant.

5.3 Spatial Out-of-Distribution Detection

Predictions far from training data are unreliable. We detect out-of-distribution (OOD) points using distance-based scoring.

OOD score for test point $\mathbf{x}_*$:

$$\mathrm{OOD}(\mathbf{x}_*) = \frac{d_{\min}(\mathbf{x}_*, \mathcal{X}_{\text{train}})}{\ell_{\text{threshold}}} \tag{24}$$

where $d_{\min}$ is distance to nearest training point and $\ell_{\text{threshold}} = 2.5 \times \ell_{\text{spatial}}$ (2.5 lengthscales).

OOD flag: $\mathrm{OOD}(\mathbf{x}_*) > 1.0$ indicates extrapolation.

Uncertainty adjustment for OOD points:

$$\sigma^2_{\text{adjusted}} = \sigma^2_{\text{base}} \times (1 + \max(0, \mathrm{OOD}(\mathbf{x}_*) - 1))^2 \tag{25}$$

Implementation:

```
from src.uncertainty import SpatialOODDetector

detector = SpatialOODDetector(
    X_train=X_train[:, :2],  # lat, lon
    lengthscales=model.kernel.lengthscales.numpy()[:2],
    threshold=2.5
)

ood_flags, ood_scores = detector.detect(X_test[:, :2])
sigma_adjusted = detector.adjust_uncertainty(sigma_base, ood_scores)

print(f"OOD points: {ood_flags.sum()} / {len(X_test)}")
```

Listing 2: OOD detection

Domain of applicability (Figure **??**): Union of circles with radius 2.5ℓ around each training point defines the reliable prediction zone for LA Basin.

Figure 5.2: Spatial Domain of Applicability

LA Basin map showing training sensor locations (blue dots) and reliable prediction zone (green shaded region). Predictions outside this domain require uncertainty inflation.

Figure 2: Domain of applicability for FusionGP in LA Basin (2023). Reliable predictions within 2.5 spatial lengthscales of training sensors.

5.4 LA Basin Implementation and Results

Dataset:

- **EPA monitors:** 50 stations (hourly)
- **PurpleAir sensors:** 200+ low-cost sensors
- **TROPOMI:** Sentinel-5P satellite AOD retrievals
- **Time period:** January–December 2023
- **Train/Test split:** 80%/20% (spatial stratification)

Hyperparameters (learned via ELBO optimization):

- Spatial lengthscale: $\ell_s = 0.08$ degrees (≈ 8 km)
- Temporal lengthscale: $\ell_t = 12$ hours
- Inducing points: $M = 500$ (K-means initialization)
- Noise variances: $\sigma^2_{\text{EPA}} = 2.1$, $\sigma^2_{\text{LC}} = 8.3$, $\sigma^2_{\text{SAT}} = 15.6$ $(\text{g/m}^3)^2$

Calibration results (Table **??**):
Key findings:

- Excellent calibration: PICP = 94.8% (target: 95%)
- Low calibration error: ECE = 0.031
- Sharp predictions: average uncertainty 8.2 g/m^3
- Epistemic uncertainty reduction via multi-source fusion: 23% lower than single-source GP

Table 2: FusionGP calibration metrics on LA Basin test set

Metric	**Value**
PICP (95%)	0.948
PICP (68%)	0.691
ECE	0.031
CRPS (g/m^3)	4.1
Sharpness (g/m^3)	8.2
RMSE (g/m^3)	6.8
Training time (min)	15
Prediction time (1000 pts, sec)	2.1

6 GAM-SSM-LUR: Hybrid Spatial-Temporal Framework

6.1 Hybrid Architecture

Additive decomposition:

$$y(\mathbf{s}, t) = \mu_{\text{GAM}}(\mathbf{s}) + \mu_{\text{SSM}}(t) + \varepsilon(\mathbf{s}, t) \tag{26}$$

Spatial component (Generalized Additive Model with Land Use Regression):

$$\mu_{\text{GAM}}(\mathbf{s}) = \beta_0 + \sum_{j=1}^{p} f_j(x_j(\mathbf{s})) \tag{27}$$

where f_j are smooth functions (cubic splines) of land use covariates:

- Road density within 100m, 500m, 1km buffers
- Traffic volume
- Elevation, land cover (urban/vegetation)
- Population density

Temporal component (State Space Model):

$$\text{Measurement:} \quad y_t = \mathbf{Z}\boldsymbol{\alpha}_t + \varepsilon_t, \quad \varepsilon_t \sim \mathcal{N}(0, H) \tag{28}$$

$$\text{State transition:} \quad \boldsymbol{\alpha}_{t+1} = \mathbf{T}\boldsymbol{\alpha}_t + \mathbf{R}\boldsymbol{\eta}_t, \quad \boldsymbol{\eta}_t \sim \mathcal{N}(0, Q) \tag{29}$$

State vector $\boldsymbol{\alpha}_t$ includes trend and seasonal components.
Parameter estimation:

1. Fit GAM on spatial covariates $\rightarrow \hat{\mu}_{\text{GAM}}(\mathbf{s})$
2. Extract spatial residuals: $r_{\text{spatial}}(t) = y(\mathbf{s}, t) - \hat{\mu}_{\text{GAM}}(\mathbf{s})$
3. Fit SSM on residuals via Expectation-Maximization $\rightarrow \hat{\mu}_{\text{SSM}}(t)$, $\mathbf{T}$, Q, H

6.2 Component Uncertainty Propagation

Spatial uncertainty from GAM prediction intervals:

$$\sigma^2_{\text{GAM}}(\mathbf{s}) = \text{Var}[\hat{\mu}_{\text{GAM}}(\mathbf{s})] \tag{30}$$

Computed via `pygam.prediction_intervals()` using approximate Bayesian covariance.
Temporal uncertainty from Kalman filter/smoother:
Prediction step:

$$\mathbf{P}_{t|t-1} = \mathbf{T}\mathbf{P}_{t-1|t-1}\mathbf{T}^T + \mathbf{R}Q\mathbf{R}^T \tag{31}$$

Update step:

$$\mathbf{K}_t = \mathbf{P}_{t|t-1}\mathbf{Z}^T(\mathbf{Z}\mathbf{P}_{t|t-1}\mathbf{Z}^T + H)^{-1} \tag{32}$$

$$\mathbf{P}_{t|t} = (\mathbf{I} - \mathbf{K}_t\mathbf{Z})\mathbf{P}_{t|t-1} \tag{33}$$

Smoothed variance (backward pass):

$$\sigma^2_{\text{SSM}}(t) = \text{diag}(\mathbf{P}_{t|T}) \tag{34}$$

where $\mathbf{P}_{t|T}$ is the RTS (Rauch-Tung-Striebel) smoothed covariance.
Combined uncertainty (assuming independence):

$$\sigma^2_{\text{total}}(\mathbf{s}, t) = \sigma^2_{\text{GAM}}(\mathbf{s}) + \sigma^2_{\text{SSM}}(t) \tag{35}$$

Testing independence assumption:

$$\rho_{\text{spatial-temporal}} = \text{Corr}(r_{\text{spatial}}, r_{\text{temporal}}) \tag{36}$$

For LA Basin: $\rho = 0.08$ ($p = 0.23$) $\Rightarrow$ independence validated.
Conservative fusion (if correlated):

$$\sigma^2_{\text{conservative}} = \sigma^2_{\text{GAM}} + \sigma^2_{\text{SSM}} + 2\rho\sigma_{\text{GAM}}\sigma_{\text{SSM}} \tag{37}$$

6.3 LA Basin Implementation and Results

Dataset: Same as FusionGP (Section **??**)
GAM configuration:

- Smooth terms: 10 splines (road density, traffic, elevation, etc.)
- Degrees of freedom: Automatically selected via GCV
- Effective DOF: 15–25 per smooth term

SSM configuration:

- State dimension: 3 (level, trend, seasonal)
- Seasonal period: 24 hours
- EM iterations: 50 (converged)

Figure 6.1: Kalman Filter Uncertainty Evolution

Temporal evolution of uncertainty over 7 days showing prediction steps (uncertainty growth) and update steps (uncertainty reduction) as measurements arrive.

Figure 3: Kalman filter uncertainty propagation for GAM-SSM-LUR. Prediction steps increase uncertainty (process noise), while measurement updates reduce it.

Table 3: GAM-SSM-LUR calibration metrics on LA Basin test set

Metric	**Value**
PICP (95%)	0.962
PICP (68%)	0.704
ECE	0.048
CRPS (g/m^3)	4.6
Sharpness (g/m^3)	9.5
RMSE (g/m^3)	7.2
Training time (min)	8
Prediction time (1000 pts, sec)	0.5

Calibration results (Table **??**):
Uncertainty breakdown:

- Mean spatial variance: $\sigma^2_{\text{GAM}} = 42.3$ (g/m^3)^2
- Mean temporal variance: $\sigma^2_{\text{SSM}} = 27.8$ (g/m^3)^2
- Spatial contribution: 60%, Temporal: 40%

Key findings:

- Good calibration: PICP = 96.2% (slightly over-conservative)
- Interpretable: Can visualize smooth functions f_j for each covariate
- Fast: 2× faster training, 4× faster inference than FusionGP
- Spatial component dominates uncertainty (land use variability)

7 Comparative Evaluation: FusionGP vs GAM-SSM-LUR

7.1 Experimental Design

Objective: Rigorous head-to-head comparison on identical datasets using standardized metrics.

Common dataset:

- LA Basin 2023 (same as individual evaluations)
- Train/Val/Test: 70%/10%/20% stratified by location
- **Spatial holdout:** 10 EPA stations completely removed from training
- **Temporal holdout:** Last 3 months (Oct–Dec 2023)

Evaluation protocol:

1. Train both models on identical training set
2. Compute predictions on same test locations/times
3. Evaluate calibration metrics (PICP, ECE, CRPS, sharpness)
4. Compare uncertainty decomposition patterns
5. Assess computational performance

7.2 Calibration Comparison

Table 4: Head-to-head calibration comparison

Metric	**FusionGP**	**GAM-SSM**	**Winner**
PICP (95%)	94.8%	96.2%	GAM-SSM
ECE	0.031	0.048	**FusionGP**
CRPS (g/m^3)	4.1	4.6	**FusionGP**
Sharpness (g/m^3)	8.2	9.5	**FusionGP**
RMSE (g/m^3)	6.8	7.2	**FusionGP**
Training (min)	15	8	**GAM-SSM**
Inference (sec)	2.1	0.5	**GAM-SSM**

Calibration curves (Figure **??**): FusionGP shows tighter alignment with perfect calibration line across all confidence levels.

7.3 Uncertainty Pattern Comparison

Spatial extrapolation test: Predictions at held-out EPA stations (15+ km from training data).

- **FusionGP with OOD adjustment:** PICP = 95.1% (well-calibrated)
- **GAM-SSM-LUR:** PICP = 89.3% (underestimates uncertainty in extrapolation)

Figure 7.1: Calibration Curves Comparison

(a) FusionGP: ECE = 0.031
(b) GAM-SSM-LUR: ECE = 0.048
Both show observed coverage vs expected coverage for multiple confidence levels.

Figure 4: Calibration quality comparison. FusionGP (left) shows tighter calibration than GAM-SSM (right), though both are well-calibrated overall.

Uncertainty decomposition differences:

- **FusionGP:** Epistemic fraction increases smoothly with distance (GP prior effect)
- **GAM-SSM:** Spatial component relatively constant (driven by covariates, not distance)

7.4 Model Selection Recommendations

Use FusionGP when:

- Spatial extrapolation beyond training data is required
- Tightest possible calibration is critical (health advisories)
- Multi-source heterogeneity is complex (varying noise characteristics)
- Computational resources are available (GPU acceleration)

Use GAM-SSM-LUR when:

- Interpretability is paramount (identifying pollution drivers)
- Faster training/inference needed (operational forecasting)
- Explicit temporal dynamics are important (diurnal/seasonal patterns)
- Infrastructure for GP methods unavailable

Both models achieve: PICP $> 94\%$, suitable for decision support.

Figure 7.2: Spatial Uncertainty Patterns

(a) FusionGP: Uncertainty vs distance from sensors
(b) GAM-SSM: Spatial vs temporal component breakdown

Figure 5: Comparison of uncertainty spatial patterns. FusionGP uncertainty increases with distance from observations, while GAM-SSM spatial uncertainty is driven by land use covariate variability.

8 Transfer Learning Uncertainty Quantification

8.1 Motivation: Geographic Domain Transfer

Models trained in one city (source domain) may need deployment in another (target domain) with limited local data. Quantifying uncertainty during transfer is critical for trustworthy predictions.

Challenge: How much uncertainty arises from:

1. Limited target data
2. Source-target distribution shift
3. Transferred model parameters

8.2 Transfer Uncertainty Decomposition

Bayesian prior tempering (**?**):

$$p(\theta|\mathcal{D}_{\text{target}}, \mathcal{D}_{\text{source}}) \propto p(\mathcal{D}_{\text{target}}|\theta) \left[p(\theta|\mathcal{D}_{\text{source}})\right]^{\beta} \tag{38}$$

where $\beta \in [0, 1]$ controls source influence ($\beta = 1$: full transfer, $\beta = 0$: no transfer).

Uncertainty decomposition:

$$\sigma^2_{\text{transfer}} = \sigma^2_{\text{target}} + \beta^2 \sigma^2_{\text{source}} + \sigma^2_{\text{domain shift}} \tag{39}$$

where:

- σ^2_{target}: Uncertainty from limited target data
- $\beta^2 \sigma^2_{\text{source}}$: Weighted source uncertainty

- $\sigma^2_{\text{domain shift}}$: Additional uncertainty from distribution mismatch

Estimating domain shift uncertainty:

$$\sigma^2_{\text{domain shift}} = \text{Var}(y_{\text{target}} - \mu_{\text{source}}) \tag{40}$$

8.3 Calibration Preservation Experiments

Experimental setup:

- Source: LA Basin (50 EPA + 200 LC sensors)
- Target: San Francisco Bay Area (10 EPA + 50 LC sensors)
- Transfer parameter: $\beta \in \{0.0, 0.3, 0.5, 0.7, 1.0\}$

Key findings (Figure **??**):

- **Baseline** ($\beta = 0.0$): PICP = 91.2% (under-calibrated due to sparse target data)
- **Optimal** ($\beta = 0.5$): PICP = 96.8% (well-calibrated)
- **Full transfer** ($\beta = 1.0$): PICP = 94.5% (over-reliance on source)

Recommendation: Moderate transfer ($\beta \approx 0.5$) balances source knowledge and target adaptation.

Figure 8.1: Transfer Parameter Selection

PICP vs transfer parameter β for LA $\rightarrow$ SF Bay Area transfer. Optimal calibration achieved at $\beta \approx 0.5$.

Figure 6: Calibration preservation during model transfer. Moderate transfer parameter ($\beta = 0.5$) achieves best calibration in target domain.

9 Practical Applications

9.1 Sensor Network Design via Uncertainty Minimization

Objective: Place new sensors to maximize uncertainty reduction.

Information gain criterion:

$$\mathrm{IG}(\mathbf{s}_{\mathrm{new}}) = H[p(\mathbf{x})] - \mathbb{E}_z\left[H[p(\mathbf{x}|z_{\mathrm{new}})]\right] \tag{41}$$

For Gaussian distributions, this simplifies to entropy reduction:

$$\mathrm{IG}(\mathbf{s}_{\mathrm{new}}) = \frac{1}{2}\log\left|\mathbf{I} + \mathbf{K}_*\boldsymbol{\Sigma}^{-1}\mathbf{K}_*^T\right| \tag{42}$$

Greedy sensor placement algorithm:

Initialize: Existing sensors $\mathcal{S}$
while budget available **do**
  Evaluate $\mathrm{IG}(\mathbf{s})$ for all candidate locations
  Select $\mathbf{s}^* = \arg\max_{\mathbf{s}} \mathrm{IG}(\mathbf{s})$
  Add $\mathbf{s}^*$ to $\mathcal{S}$
  Update uncertainty map with new sensor
end while

LA Basin case study: Adding 10 low-cost sensors reduced average epistemic uncertainty by 18% (from 8.2 to 6.7 g/m^3).

9.2 Health Advisories with Uncertainty-Aware Thresholds

Problem: EPA Air Quality Index (AQI) uses point estimates. Should we use upper confidence bound for conservative health protection?

Decision rule:

$$\mathrm{AQI}_{\mathrm{conservative}} = f(\mu + z_\alpha\sigma) \tag{43}$$

where z_α is chosen based on risk tolerance (e.g., $z_{0.95} = 1.645$ for 95% upper bound).

Example:

- Point estimate: $\mu = 35$ g/m^3 $\rightarrow$ AQI = Moderate (Yellow)
- Uncertainty: $\sigma = 10$ g/m^3
- 95% upper bound: $35 + 1.645 \times 10 = 51.5$ g/m^3 $\rightarrow$ AQI = Unhealthy for Sensitive (Orange)

Recommendation: Use upper bound for vulnerable populations (children, elderly), point estimate for general advisories.

9.3 Model Selection Decision Tree

10 Limitations and Future Work

10.1 Current Limitations

1. **Hyperparameter uncertainty not fully quantified:**
   - Both models use point estimates for hyperparameters (lengthscales, noise variances)

Figure 9.1: Model Selection Decision Tree

Decision flowchart for choosing between FusionGP and GAM-SSM-LUR based on application requirements (interpretability, computational resources, extrapolation needs).

Figure 7: Decision tree for selecting between FusionGP and GAM-SSM-LUR based on application context.

- May underestimate total uncertainty by 10–30% in sparse data regions
- **Mitigation:** Bootstrap ensemble (20 models) can approximate hyperparameter uncertainty

2. **Computational cost for real-time systems:**
   - FusionGP requires GPU for $N > 10^5$ observations
   - Inference latency: 2 sec for 1000 predictions
   - **Mitigation:** Pre-compute predictions on regular grid, interpolate
3. **Stationarity assumptions:**
   - Fixed lengthscales assume constant spatial correlation
   - Temporal patterns may be non-stationary (e.g., wildfire season)
   - **Mitigation:** Time-varying kernels or seasonal re-training
4. **Independence assumption in GAM-SSM:**
   - Validated for LA Basin ($\rho = 0.08$), but may not hold elsewhere
   - Conservative fusion adds computational overhead

10.2 Future Directions

1. **Deep learning UQ:**
   - Bayesian neural networks for non-stationary patterns
   - Uncertainty-aware convolutional networks for satellite imagery
   - Conformal prediction for distribution-free calibration guarantees
2. **Multi-pollutant fusion:**
   - Joint modeling of $PM_{2.5}$, NO_2, O_3 with correlation structure
   - Multi-output GPs for cross-pollutant uncertainty
3. **Active learning for adaptive sampling:**
   - Deploy mobile sensors to high-uncertainty regions
   - Real-time uncertainty-driven sensor placement
4. **Causal uncertainty quantification:**
   - Distinguish correlation from causation in covariate effects
   - Counterfactual predictions with uncertainty (e.g., emission reduction scenarios)

11 Conclusion

This chapter developed a comprehensive framework for uncertainty quantification in multi-source air quality sensor fusion, comparing two complementary probabilistic approaches:

FusionGP (Sparse Variational GP):

- Principled Bayesian framework with epistemic/aleatoric decomposition
- Superior calibration (ECE = 0.031) and sharp predictions (8.2 g/m^3)
- Excellent spatial extrapolation with OOD-adjusted uncertainty
- Best for applications requiring tight calibration and multi-source heterogeneity

GAM-SSM-LUR (Hybrid spatial-temporal):

- Interpretable smooth functions reveal pollution drivers
- Good calibration (PICP = 96.2%) with explicit temporal dynamics
- Computationally efficient (2× faster training, 4× faster inference)
- Best for operational forecasting and stakeholder communication

Key findings:

1. Both models achieve well-calibrated predictions (PICP > 94%)
2. Epistemic uncertainty dominates (60–80%) far from observations, indicating where new sensors are most valuable

3. Moderate transfer learning ($\beta \approx 0.5$) preserves calibration across geographic domains
4. Automated OOD detection improves coverage from 87% to 95% for extrapolated predictions

Practical impact:

- Uncertainty-aware health advisories protect vulnerable populations
- Information-driven sensor placement optimizes network design
- Open-source implementations enable reproducibility and adoption

Future work includes hyperparameter uncertainty quantification via bootstrap ensembles, deep learning UQ for non-stationary patterns, and multi-pollutant joint modeling.

The methods and code presented here provide a foundation for trustworthy probabilistic predictions in environmental monitoring, with broad applicability beyond air quality to other sensor fusion problems requiring rigorous uncertainty quantification.

A Implementation Details

Code available at: `https://github.com/GabrielOduori/uncertainty_quantification`

A.1 Software Dependencies

- Python 3.9+
- GPflow 2.9+ (SVGP implementation)
- PyGAM 0.9+ (GAM implementation)
- NumPy, SciPy, Pandas (scientific computing)
- Matplotlib, Seaborn (visualization)

A.2 Reproducibility

All experiments use fixed random seeds. Data and trained models available upon request.
